Figure 5.3. Schematic of a laboratory tunable diode laser system: L1 and L2 are the lenses used to focus the beam onto the White cell entrance and the detector, respectively, and PM1–PM5 are gold-coated mirrors used for beam alignment.
Lock-In-Verstärker

\[ U_{out} = U(\Delta) = \frac{ab}{2} \cos(\Delta) \]
Lock-In-Verstärker

Consider the case where a noise-free sinusoidal signal voltage $V_{in}$ is being detected, where

$$V_{in} = A \cos (\omega t)$$

$\omega$ is the angular frequency of the signal which is related to the frequency, $F$, in hertz by the equality:-

$$\omega = 2 \pi F$$

The lock-in amplifier is supplied with a reference signal at frequency $F$ derived from the same source as the signal, and uses this to generate an internal reference signal of:-

$$V_{ref} = B \cos (\omega t + \theta)$$

where $\theta$ is a user-adjustable phase-shift introduced within the lock-in amplifier.

The detection process consists of multiplying these two components together so that the PSD output voltage is given by:-

$$V_{psd} = A \cos (\omega t) . B \cos (\omega t + \theta)$$

$$= AB \cos \omega t \cos \omega t \cos \theta - \sin \omega t \sin \theta$$

$$= AB \cos 2\omega t \cos \theta - \cos \omega t \sin \omega t \sin \theta$$

$$= AB (\frac{1}{2} + \frac{1}{2} \cos 2\omega t) \cos \theta - \frac{1}{2} \sin 2\omega t \sin \theta$$

$$= \frac{1}{2} AB((1 + \cos 2\omega t) \cos \theta - \sin 2\omega t \sin \theta)$$

$$= \frac{1}{2} AB(\cos \theta + \cos 2\omega t \cos \theta - \sin 2\omega t \sin \theta)$$

$$= \frac{1}{2} AB \cos \theta + \frac{1}{2} AB \cos(2\omega t + \theta)$$

If the magnitude, B, of the reference frequency is kept constant, then the output from the phase-sensitive detector is a DC signal which is:-

- proportional to the magnitude of the input signal $A$
- proportional to the cosine of the angle, $\theta$, between it and the reference signal
- modulated at $2\omega t$, i.e. it contains components at twice the reference frequency.

The output from the PSD then passes to a low-pass filter which removes the $2\omega t$ component, leaving the output of the lock-in amplifier as the required DC signal.

In a practical situation the signal will usually be accompanied by noise, but it can be shown that as long as there is no consistent phase (and therefore by implication frequency) relationship between the noise and the signal, the output of the multiplier due to the noise voltages will not be steady and can therefore be removed by the output filter.

Figure 2.5. Overview of UV-visible spectral ranges usable for the detection of atmospheric trace gases. Vertical scale: log of absorption cross section of the molecule ($10^{-20}$ to $10^{-17}$ cm$^2$/molecule); also approximate detection limit at 10 km light path length (1 ppt to 1 ppb, see insert). Molecules exhibiting strong rotational structure at atmospheric pressure are denoted by an asterisk (*).
DOAS: Differential Optical Absorption Spectroscopy

Figure 2.13. Deconvolution process of an air spectrum with overlapping NO₂, O₃, and CH₂O absorptions. This example shows an atmospheric absorption spectrum from 325 to 350 nm taken at Jülich, Germany (top trace). The most dominant absorption features are due to NO₂ (NO₂ reference spectrum, second trace from top). Three reference spectra due to NO₂, O₃, and CH₂O, respectively, were simultaneously fitted to the atmospheric spectrum. Using the coefficients thus determined, one can subtract the suitable scaled logarithms of the NO₂ and CH₂O reference spectra, leaving a residual spectrum clearly showing O₃ absorption features (two center traces). An analogous operation with the NO₂ and O₃ reference spectra shows that CH₂O absorption features are also present in the spectrum (two bottom traces). Adapted from Platt and Perner (1983).
